Containerizing Microservices with Docker

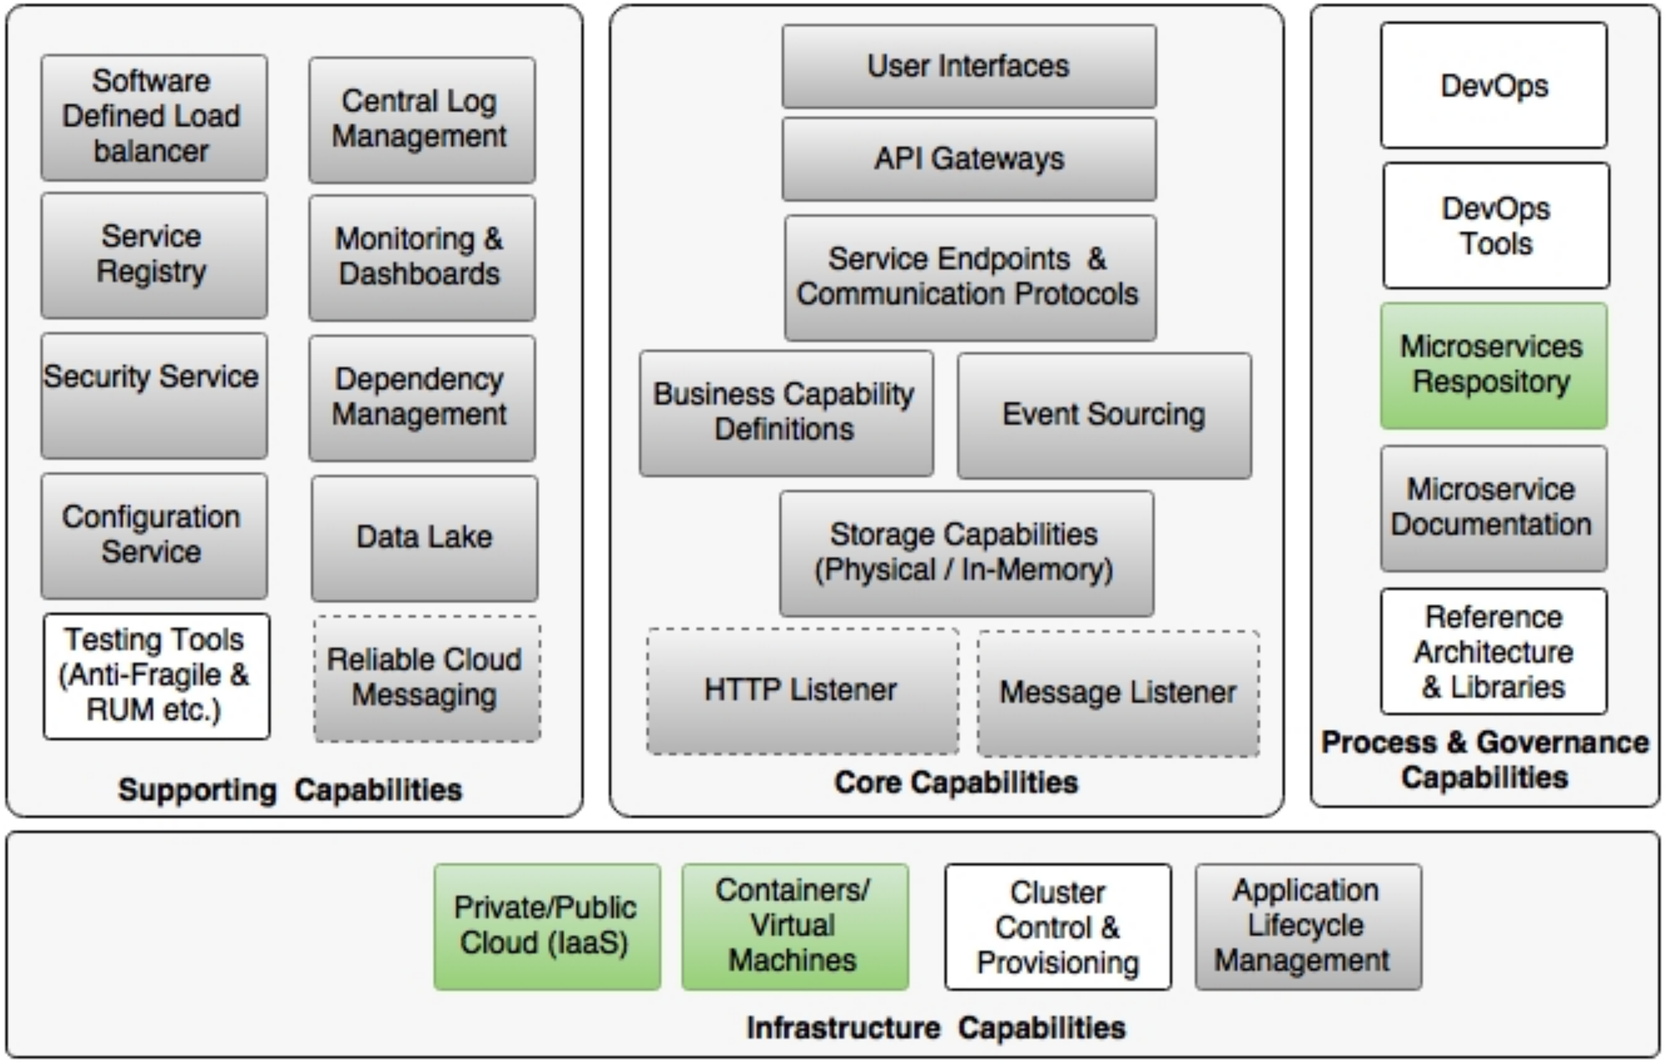
Context

- In the context of microservices, containerized deployment is the icing on the cake
- It helps microservices be more autonomous by self-containing the underlying infrastructure, thereby making the microservices cloud neutral

Topics

- The concept of containerization and its relevance in the context of microservices
- Building and deploying microservices as Docker images and containers
- Using AWS as an example of cloud-based Docker deployments

Reviewing the microservice capability model



Understanding the gaps in BrownField PSS microservices

- Lecture 6: Scaling Microservices with Spring Cloud, BrownField PSS microservices were developed using Spring Boot and Spring Cloud. These microservices are deployed as versioned fat JAR files on bare metals, specifically on a local development machine
- Lecture 7: Autoscaling Microservices, the autoscaling capability was added with the help of a custom life cycle manager
- Lecture 8: Logging and Monitoring Microservices, challenges around logging and monitoring were addressed using centralized logging and monitoring solutions

Understanding the gaps in BrownField PSS microservices

- There are still a few gaps
- The implementation has not used any cloud infrastructure
- A cloud infrastructure provides all the essential capabilities
- Running multiple microservices on a single bare metal could lead to a "noisy neighbor" problem
- An alternate approach is to run the microservices on VMs. However, VMs are heavyweight in nature
- In the case of Java-based microservices, sharing a VM or bare metal to deploy multiple microservices also results in sharing JRE among microservices
  - The fat JARs created in our BrownField PSS abstract only application code and its dependencies but not JREs

Understanding the gaps in BrownField PSS microservices

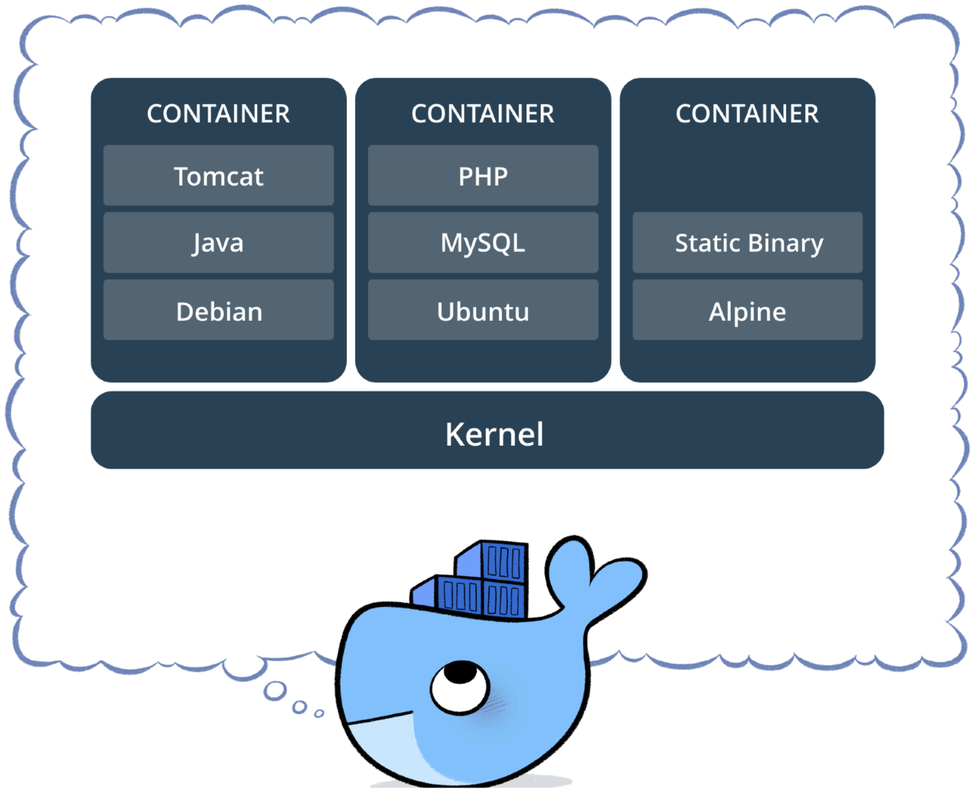
- One microservice principle insists that it should be self-contained and autonomous by fully encapsulating its end-to-end runtime environment
- In order to align with this principle, all components, such as the OS, JRE, and microservice binaries, have to be self-contained and isolated
- The only option to achieve this is to follow the approach of deploying one microservice per VM
- However, this will result in underutilized virtual machines, and in many cases, extra cost due to this can nullify benefits of microservices

What are containers?

- CONTAINERS ARE PROCESSES
- Containers are processes sandboxed by:
  - Kernel namespaces
  - Root privilege management
  - System call restrictions
  - Private network stacks
  - etc

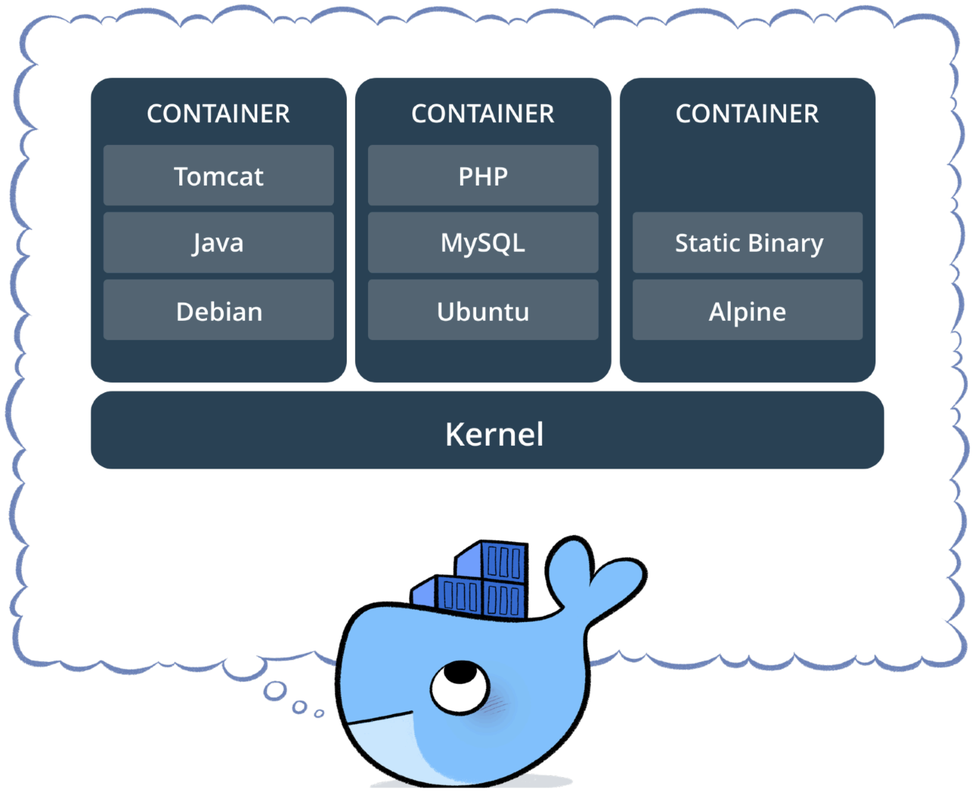
What are containers?

- Containers provide private spaces on top of the operating system
- This technique is also called operating system virtualization
  - The kernel of the operating system provides isolated virtual spaces
  - Each of these virtual spaces is called a container or virtual engine (VE)
- Containers allow processes to run on an isolated environment on top of the host operating system



What are containers?

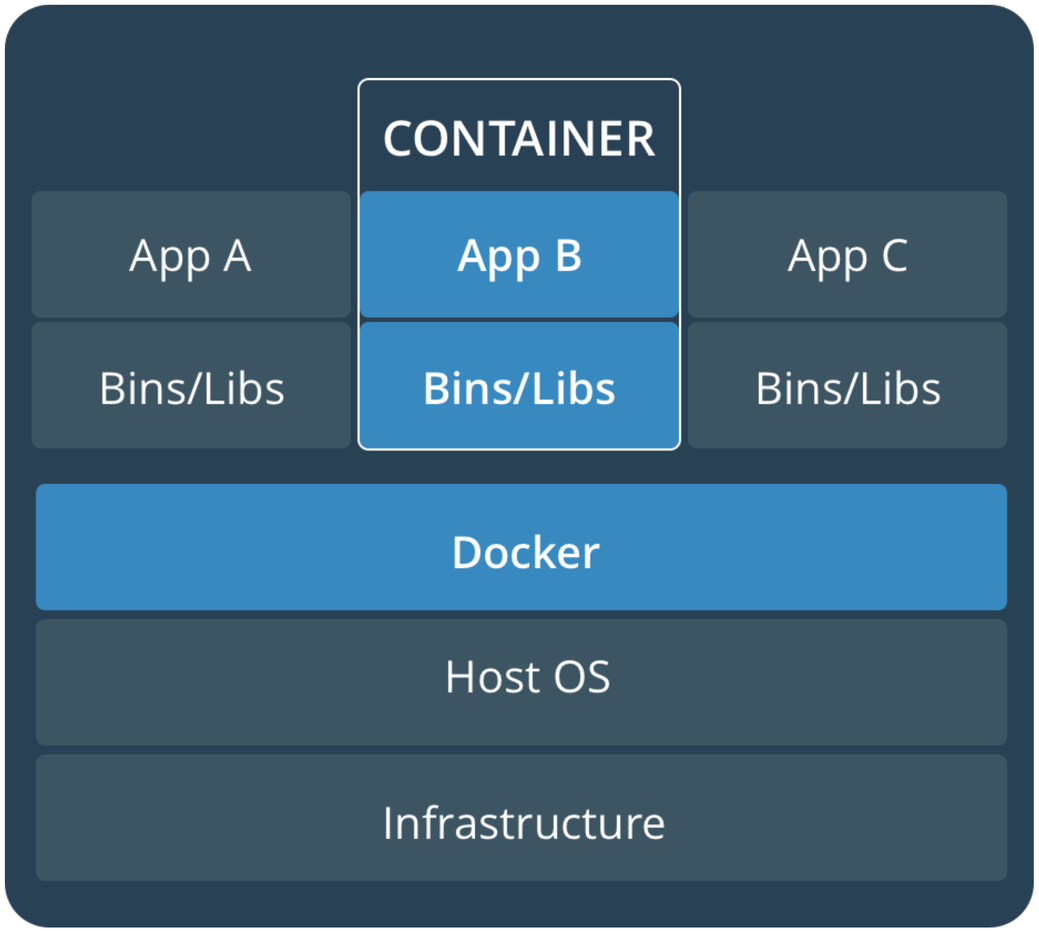
- Containers are easy mechanisms to build, ship, and run compartmentalized software components
- Generally, containers package all the binaries and libraries that are essential for running an application
- Containers reserve their own filesystem, IP address, network interfaces, internal processes, namespaces, OS libraries, application binaries, dependencies, and other application configurations

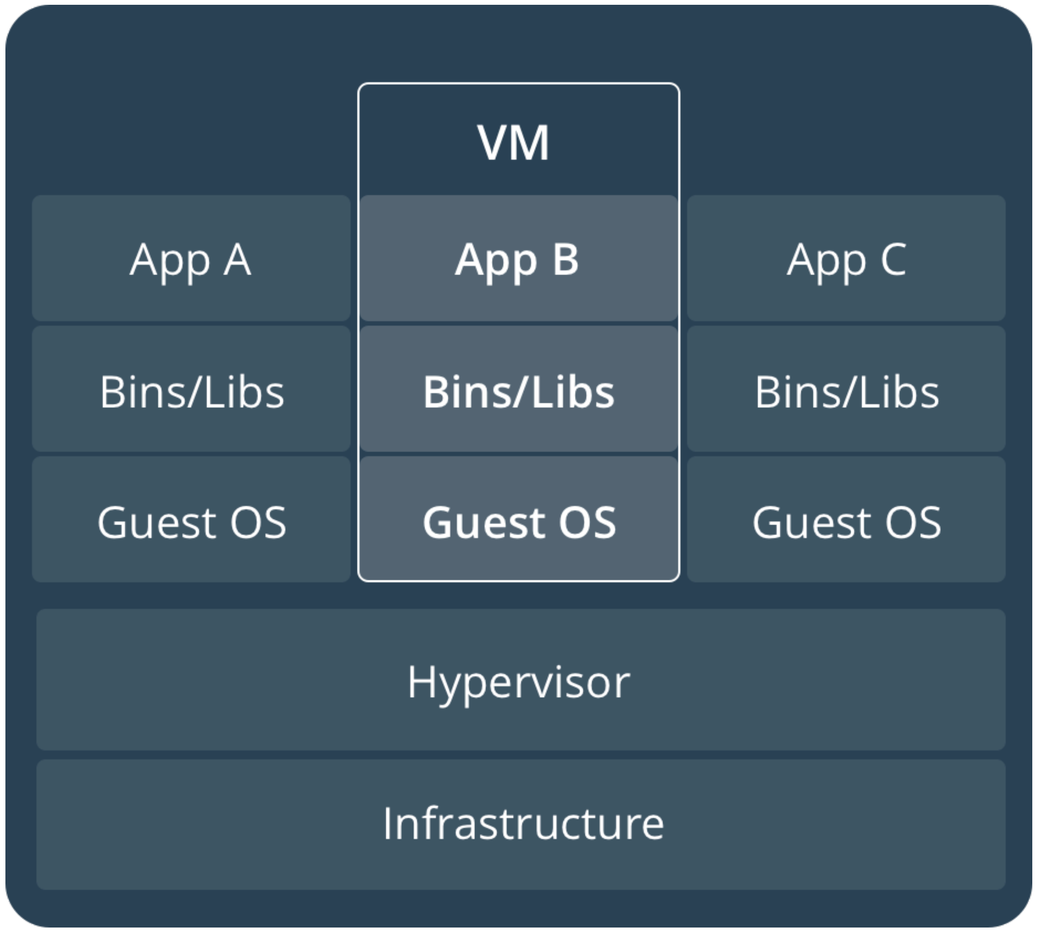


Big white shark?

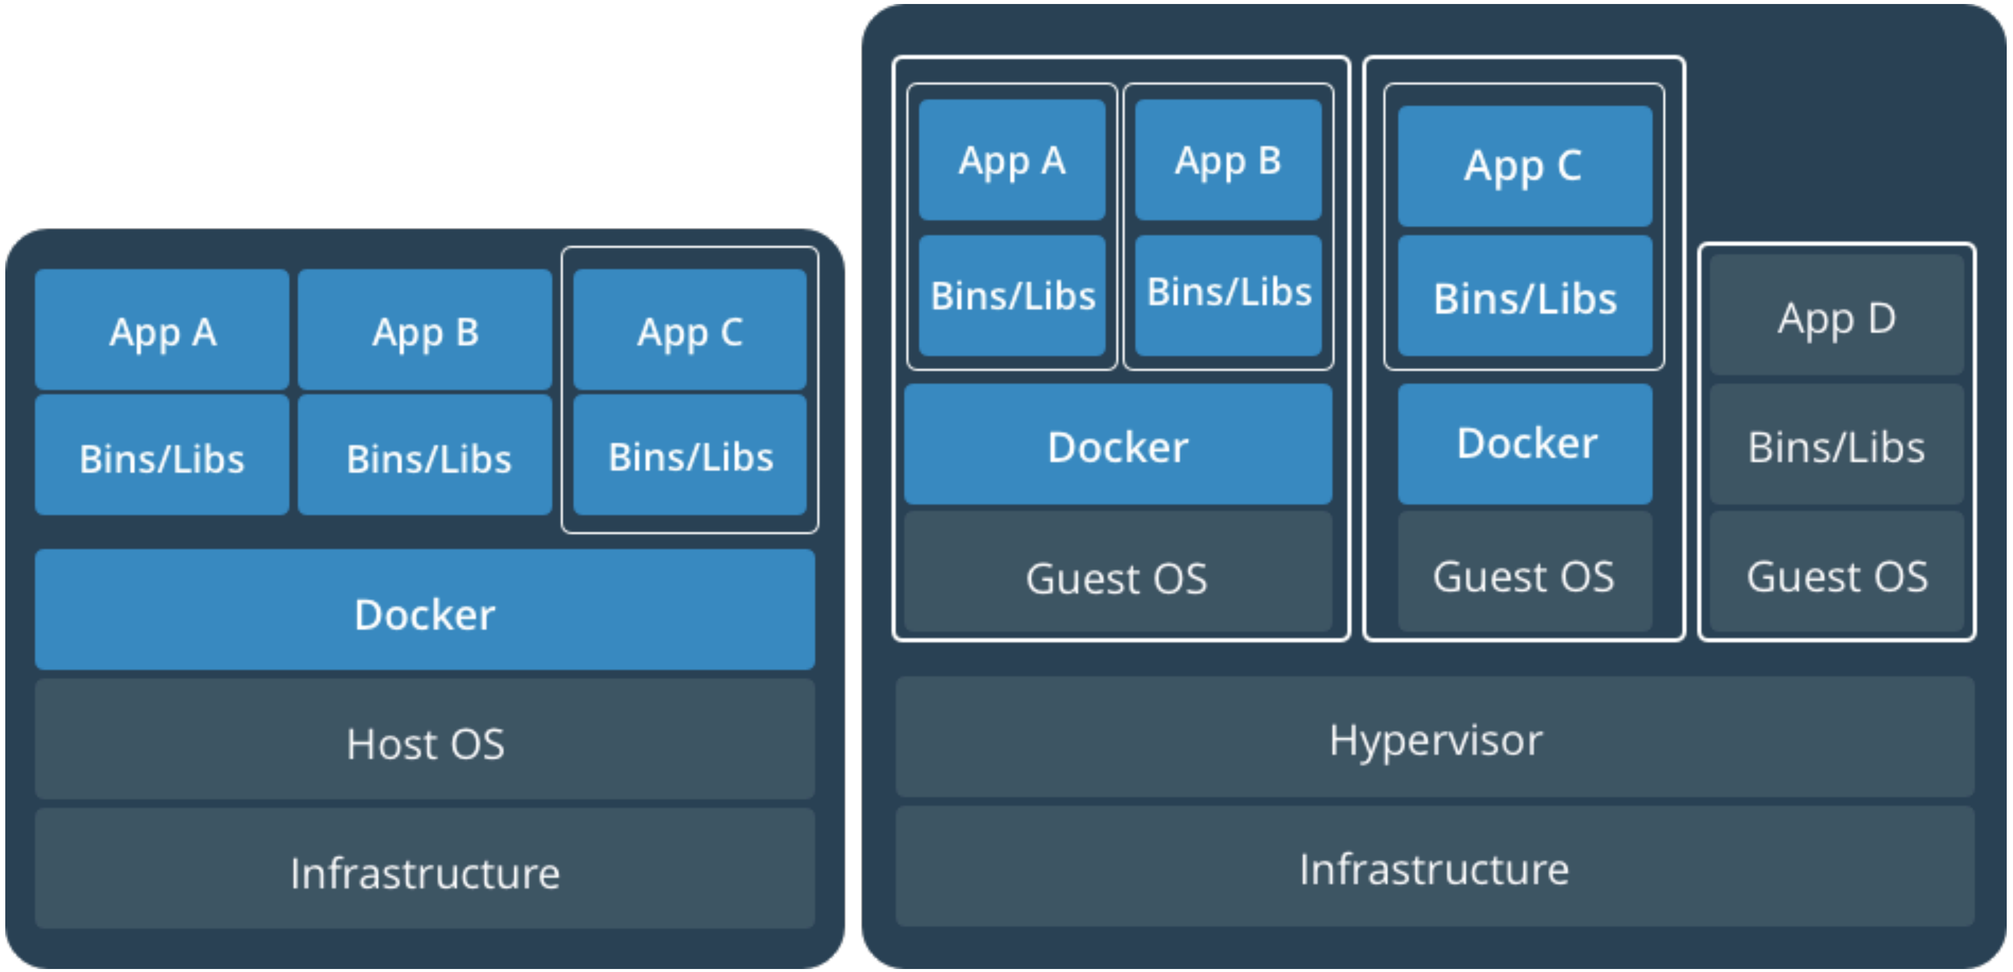
- There are billions of containers used by organizations
- Moreover, there are many large organizations heavily investing in container technologies
- Docker is far ahead of the competition, supported by many large operating system vendors and cloud providers
- Lmctfy, SystemdNspawn, Rocket, Drawbridge, LXD, Kurma, and Calico are some of the other containerization solutions
- Open container specification is also under development

The difference between VMs and containers

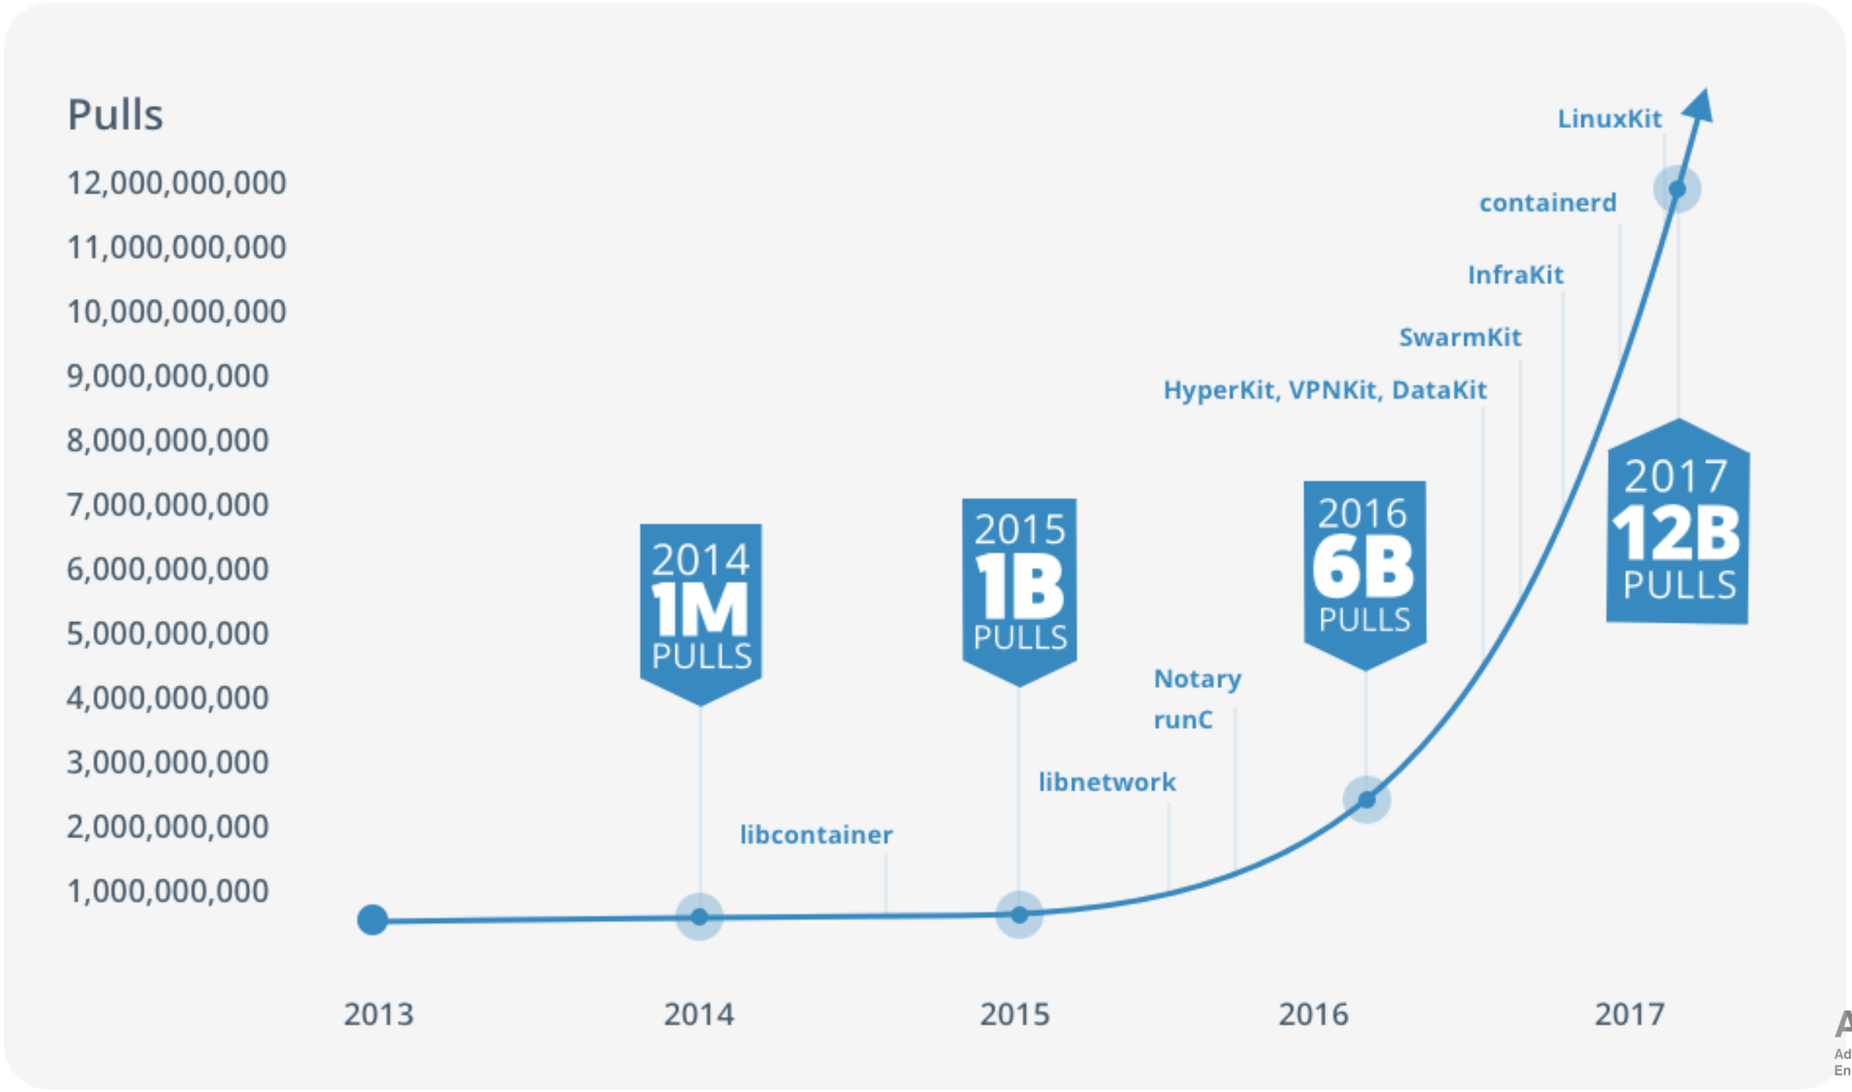




Containers and Virtual Machines Together



Container Standards and Industry Leadership



The benefits of containers

- Self-contained: package the essential application binaries and their dependencies together
- Lightweight: containers, in general, are smaller in size with a lighter footprint.
  - The simplest Spring Boot microservice packaged with an Alpine container with Java 8 would only come to around 170 MB in size
- Scalable: container images are smaller in size and there is no OS booting at startup
- Portable: are built with all the dependencies, they can be ported across multiple machines or across multiple cloud providers
- Lower license cost: Many software license terms are based on the physical core

The benefits of containers

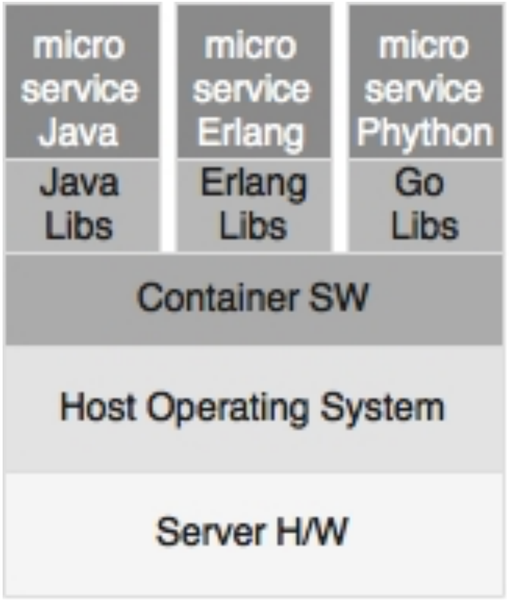
- DevOps: the lightweight footprint of containers makes it easy to automate builds and publish and download containers from remote repositories
- Version controlled: support versions by default
- Reusable: container images are reusable artifacts
- Immutable containers: containers are created and disposed of after usage, they are never updated or patched
  - Immutable containers are used in many environments to avoid complexities in patching deployment units
  - Patching results in a lack of traceability and an inability to recreate environments consistently

Microservices and containers

- Microservices can run without containers, and containers can run monolithic applications
- Containers are good for monolithic applications
  - but the complexities and the size of the monolith application may kill some of the benefits of the containers

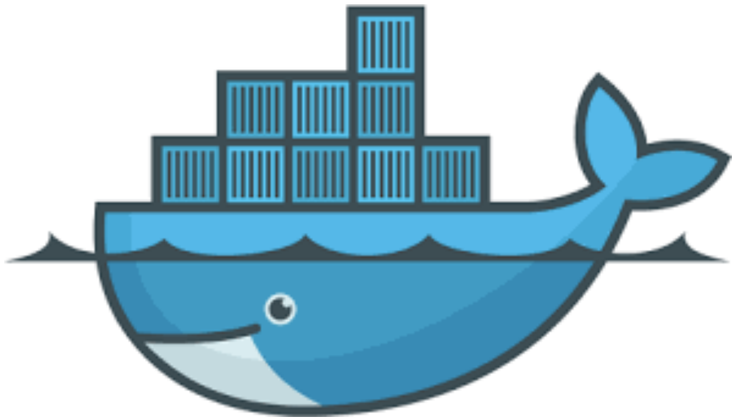
Microservices and containers

- The real advantage of containers can be seen when managing many polyglot microservices
- Eliminate the need to have different deployment management tools to handle polyglot microservices
- Not only abstract the execution environment but also how to access the services
- Irrespective of the technologies used, containerized microservices expose REST APIs
- Once the container is up and running, it binds to certain ports and exposes its APIs
- As containers are self-contained and provide full stack isolation among services, in a single VM or bare metal, one can run multiple heterogeneous microservices and handle them in a uniform way



Introduction to Docker

- Containers have been in the business for years, but the popularity of Docker has given containers a new outlook
- As a result, many container definitions and perspectives emerged from the Docker architecture
- Docker is so popular that even containerization is referred to as dockerization
- Docker is a platform to build, ship, and run lightweight containers based on Linux kernels



Security

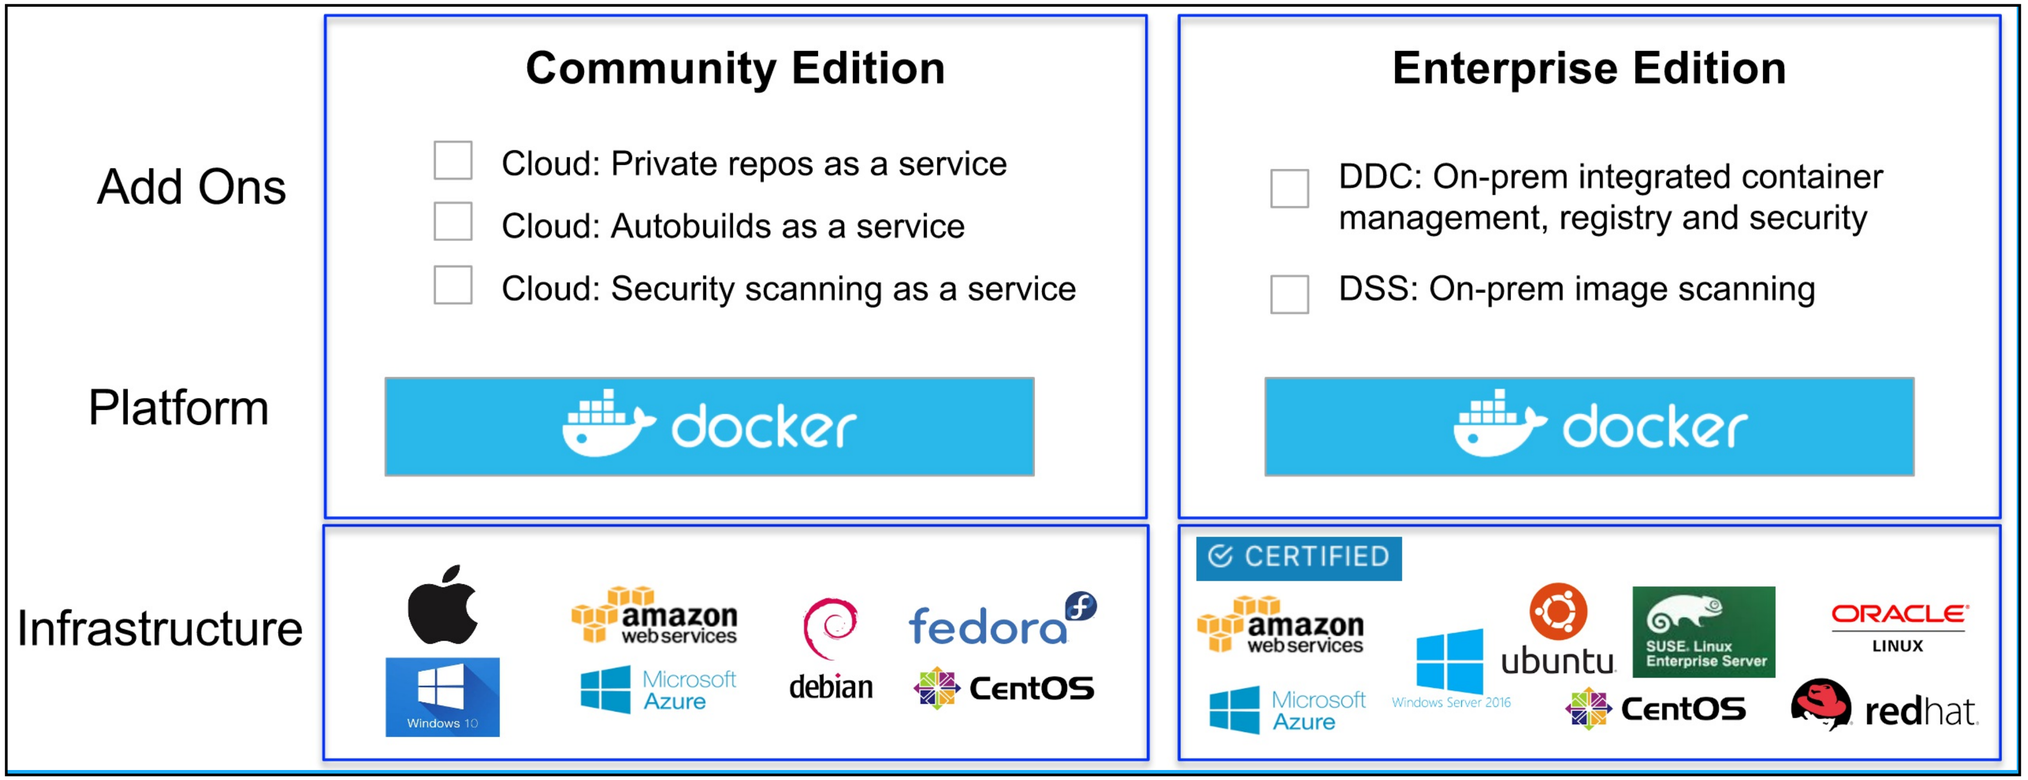
"Gartner asserts that applications deployed in containers are more secure than applications deployed on the bare OS."

http://blogs.gartner.com/joerg-fritsch/can-you-operationalize-docker-containers/

Introduction to Docker

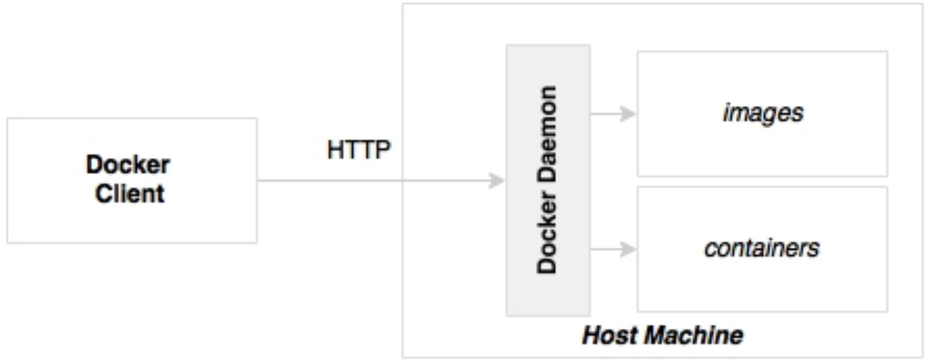
- The most basic thing Docker provides is a
- FRAMEWORK FOR SERVICE ENCAPSULATION
- But what are the implications of this for developers, ops, and orgs?

Docker Product Offerings



The key components of Docker

- The Docker daemon is a server-side component that runs on the host machine responsible for building, running, and distributing Docker containers
  - exposes APIs for the Docker client to interact with the daemon. These APIs are primarily REST-based endpoints
- The Docker client is a remote command-line program that interacts with the Docker daemon through either a socket or REST APIs
  - Docker users use the CLI to build, ship, and run Docker containers

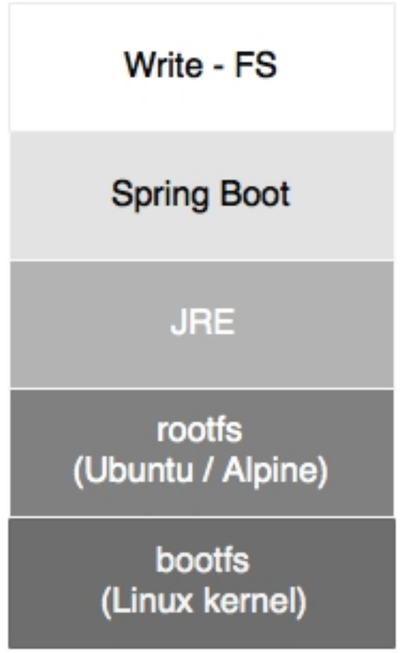


Docker concepts

- A Docker image is the read-only copy of the operating system libraries, the application, and its libraries
- Once an image is created, it is guaranteed to run on any Docker platform without alterations
- In Spring Boot microservices, a Docker image packages operating systems such as Ubuntu, Alpine, JRE, and the Spring Boot fat application JAR file
  - Docker images are based on a layered architecture in which the base image is one of the flavors of Linux
  - Each layer, as shown in the preceding diagram, gets added to the base image layer with the previous image as the parent layer
  - Docker uses the concept of a union filesystem to combine all these layers into a single image, forming a single filesystem

Docker image

- Every time we rebuild the application, only the changed layer gets rebuilt, and the remaining layers are kept intact
- Multiple containers running on the same machine with the same type of base images would reuse the base image, thus reducing the size of the deployment
- For instance, in a host, if there are multiple containers running with Ubuntu as the base image, they all reuse the same base image



Docker image

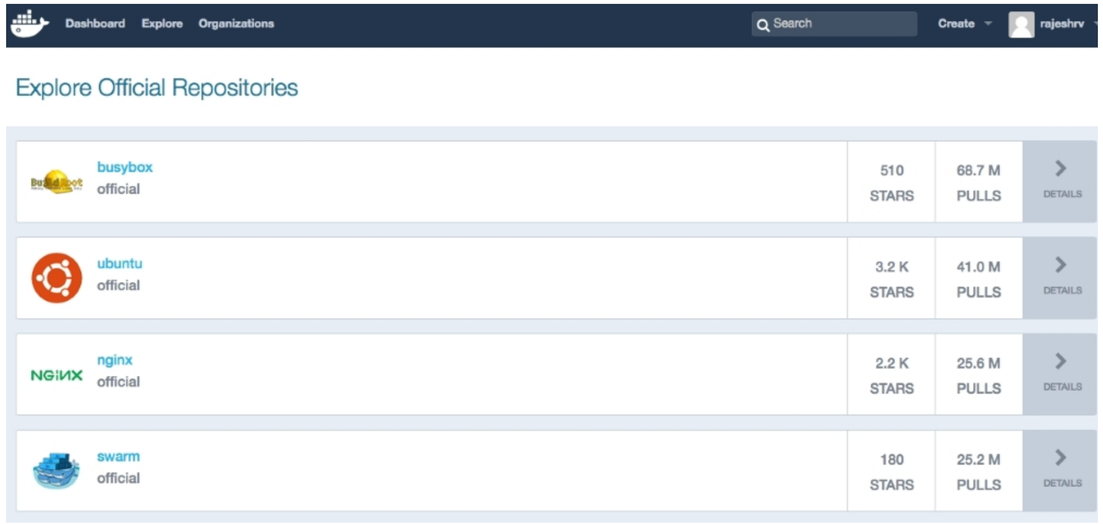
- IMAGES ARE LAYERED FILESYSTEMS
- Provide filesystem for container process
- Image = stack of immutable layers
- Start with a base image
- Add layer for each change

Docker containers

- Docker containers are the running instances of a Docker image
- Containers use the kernel of the host operating system when running
  - Hence, they share the host kernel with other containers running on the same host
- The Docker runtime ensures that the container processes are allocated with their own isolated process space using kernel features such as **cgroups** and the kernel **namespace** of the operating system
-

The Docker registry

- The Docker registry is a central place where Docker images are published and downloaded from
- The URL https://hub.docker.com is the central registry provided by Docker
- The Docker registry has public images that one can download and use as the base registry
- Docker also has private images that are specific to the accounts created in the Docker registry



Dockerfile

- A Dockerfile is a build or scripting file that contains instructions to build a Docker image
- There can be multiple steps documented in the Dockerfile, starting from getting a base image
- The docker build command looks up Dockerfile for instructions to build
- One can compare a Dockerfile to a pom.xml file used in a Maven build

Dockerfile

- FROM command defines base image
- Each subsequent command adds a layer
- docker image build ... builds image from Dockerfile

```
# Comments begin with the pound sign
FROM ubuntu:16.04
RUN apt-get update
ADD /data /myapp/data
...
```

Homework 11.1

- A guided tour to deploying microservices in Docker

The future of containerization – unikernels and hardened security

- Containerization is still evolving, but the number of organizations adopting containerization techniques has gone up in recent times
- Currently, Docker images are generally heavy
  - In an elastic automated environment, where containers are created and destroyed quite frequently, size is still an issue
  - A larger size indicates more code, and more code means that it is more prone to security vulnerabilities

The future of containerization – unikernels and hardened security

- The future is definitely in small footprint containers
- Docker is working on unikernels, lightweight kernels that can run Docker even on low-powered IoT devices
  - Unikernels are not full-fledged operating systems, but they provide the basic necessary libraries to support the deployed applications

The future of containerization – unikernels and hardened security

- The security issues of containers are much discussed and debated
- The key security issues are around the user namespace segregation or user ID isolation
- If the container is on root, then it can by default gain the root privilege of the host
- Using container images from untrusted sources is another security concern
- Docker is bridging these gaps as quickly as possible, but there are many organizations that use a combination of VMs and Docker to circumvent some of the security concerns
